INTRODUCTION

Some 5-20 % of radiotherapy treatments for pelvic tumours may cause a vascular rectal injury. Endoscopic treatments, fundamentally argon plasma coagulation (APC), are the most effective, but there are refractory cases and complications (1).

CASE REPORT

Male, 75-years-old. Cirrhosis and secondary thrombocytopenia. Eight months after radiation therapy for prostate adenocarcinoma, he presented actinic proctitis (AP) with severe rectal bleeding (haemoglobin 6.6 g/dL, platelets 28,000/mm³). After five sessions of APC and sucralfato, haemostasis was not achieved producing iatrogenic rectal ulcers (Fig. 1). He received 15 red blood cell packs and 2 platelets pools.

Ablation of the rectal mucosa with radiofrequency, Halo 60º system, was proposed. Using a gastroscope at whose end was inserted the radiofrequency device, and with patient under propofol sedation, we applied power of 12 J/cm² and a density of 40 w, twice per area, with direct and retroverted view (Figs. 2 and 3). Only half the circumference was treated, to avoid stenosis, and also avoiding anorectal line. The patient’s tolerance was very good. After the first session control of bleeding was achieved. A second session was scheduled at 4 weeks, but because of an intercurrent neurological process, was delayed at 7 weeks, and untreated mucosa ablation was performed. The third session, four weeks later, addressed residual...
vascular lesions. At 10 weeks we verified the disappearance of neovessels and extensive reepithelialization (Fig. 4) that, in the area closest to the anal margin, was similar to endoanal mucosa and without complications. The patient has remained asymptomatic 8 months later.

DISCUSSION

The radiofrequency is used in the context of Barrett’s esophagus, and also its usefulness has been described in some cases of antral vascular ectasia and AP (2-4).

We report a refractory AP bleeding in which mucosa ablation achieved maintained haemostasis. Destruction of most vascular lesions was achieved, yielding good reepithelialisation without complications.

Twice 12 J/cm² per area has demonstrated no involvement of the colonic serosa limiting involvement of the muscularis propria (5), and probably the low penetration make the ulcers or stenosis less likely than with other techniques.

Only three published articles have reported the usefulness of radiofrequency, using the Halo 90⁰, in this clinical entity (2-4). Using a small device, the Halo 60⁰, provides better manœuvreability and a good visibility, facilitating getting as close as possible to the anorectal line without damaging it and it allows to treat wider areas than APC. Although because its cost is higher, should be reserved for cases refractory to conventional endoscopic treatment.
